ABSTRACT

Motivation: Boolean network models are suitable to simulate gene regulatory networks (GRNs) in the absence of detailed kinetic information. However, reducing the biological reality implies making assumptions on how genes interact (interaction rules) and how their state is updated during the simulation (update scheme). The exact choice of the assumptions largely determines the outcome of the simulations. In most cases, however, the biologically correct assumptions are unknown. An ideal simulation thus implies testing different rules and schemes to determine those that best capture an observed biological phenomenon. This is not trivial, since most current methods to simulate Boolean network models of GRNs and to compute their attractors impose specific assumptions that cannot be easily altered, as they are built into the system.

Results: To allow for a more flexible simulation framework, we developed ASP-G. We show the correctness of ASP-G in simulating Boolean network models and obtaining attractors under different assumptions by successfully recapitulating the detection of attractors of previously published studies. We also provide an example of how performing simulation of network models under different settings help determine the assumptions under which a certain conclusion holds. The main added value of ASP-G is in its modularity and declarativity, making it more flexible and less error-prone than traditional approaches. The declarative nature of ASP-G comes at the expense of being slower than the more dedicated systems but still achieves a good efficiency w.r.t. computational time.

1 INTRODUCTION

Gene Regulatory Networks (GRNs) consist of genes, proteins and other regulatory molecules that undergo complex and dynamic interactions which drive gene expression, and ultimately, complex cellular behaviour. To be able to understand and predict this behaviour, various mathematical models have been developed that describe the dynamics of these GRNs. Different model formalisms have been used, as reviewed in De Jong (2002). One of the earliest models to describe GRNs are Boolean network models (Kauffman (1993)). Boolean network models are attractive because of their simplicity (Shmulevich et al. (2002)): by reducing the complexity of GRNs to qualitative logical models, Boolean network models are able to cope with the largely incomplete kinetic information of biological networks. Despite their highly simplified representation of biological reality, Boolean network models were shown to still grasp the important dynamic properties of GRNs, such as the networks’ attractors. An attractor represents a stable set of states towards which the transiently changing gene expression values converge to. Evolving towards an attractor thus corresponds to reaching a specific developmental stage (cell types, development stages of cells, etc) or functional mode (De Jong and Page (2008), Kauffman (1993)), and the analysis of attractors in a regulatory network thus hints towards the functional modes of the regulatory network (De Jong and Page (2008)).
Current knowledge regarding GRNs are generally incomplete (Rottger et al. (2012)). Comparing simulated with observed attractors (states, e.g. developmental stages) of a certain network model can thus aid in evaluating existing network models and/or predict missing information in the current knowledge. For instance, Mendoza and Alvarez-Buylla (1998), Mendoza et al. (1999) and more recently, Espinosa-Soto et al. (2004) and Sanchez-Corrales et al. (2010) studied flower development in Arabidopsis thaliana using Boolean network models of which the network attractors corresponded to stable gene expression levels during the different stages of flower development. These models helped predicting mutant phenotypes and the existence of a yet-uncharacterized gene involved in the transition from the non-flowering to the flowering state. Li et al. (2004) and Davidich and Bornholdt (2008) used a Boolean network model and its steady states to describe the different stages in yeast cell cycle, where the stages of the cycle correspond to the strong attractors of the network. Kaufman et al. (1985) explained the various states of the immune system with Boolean network models and Sánchez and Thieffry (2001), Albert and Othmer (2003) and González et al. (2008) used Boolean network models and their attractors to describe the cellular development of Drosophila melanogaster.

Key to simulating GRNs with Boolean network models is the choice of the proper assumptions. These assumptions refer to the activation rules and update scheme. Activation rules determine the way the activation state of each gene depends on the activation states of its interactors in the previous transition step. The update scheme determines how these activation states are updated, i.e. either synchronously or asynchronously. The exact choice of these assumptions largely determines the number and characteristics of the attractors. As in most cases, the true biological activation rules and update scheme are not known, one should be able to easily test different activation rules and schemes, as this allows to have an idea on the conditions under which the simulated network model would be able to capture an observed biological phenomena (boundary conditions).

Several computational tools have been developed to perform the computation of attractors in Boolean network models. Garg et al. (2007) developed genYsis, which uses techniques involving Binary Decision Diagrams (BDD) to compute attractors. Arellano et al. (2011) used techniques based on Temporal Logic model checking in Antelope. Ay et al. (2009) used state-space pruning and randomized state-space traversal methods to improve the scalability of the attractor computation. Dubrova and Teslenko (2011) used a Boolean Satisfiability (SAT) solver, typically used for combinatorial modeling and problem solving, to compute attractors of GRNs and obtained a better computational time and space efficiency compared to the BDD-based approach. More recently, Zheng et al. (2013) developed geneFast based on the Reduced Order BDD (ROBDD) data structure which further improves the efficiency of the attractor computation.

Most of the above-mentioned systems to simulate Boolean network models in principle can perform simulations with different assumptions. However, changing these assumptions would require quite tedious modifications on these systems. For instance, using the SAT-approach (Dubrova and Teslenko (2011)), modifying the structure of the network and the updating rules would require updating the truth tables in the cnet format.

To allow for a more flexible simulation framework we developed ASP-G which makes use of the declarative-programming paradigm Answer Set Programming (ASP) (Lifschitz (2008)). The declarative nature of ASP allows one to specify and modify the domain-specific logic (here the definition of the network interactions, activation rules and update schemes) required to represent and solve the computational problem at hand (here dynamical modeling and attractor calculation) in an intuitive and modular way (Eiter et al. (2009)). To illustrate the flexibility of our approach, we applied it to calculate attractors of previously published Boolean network models of GRNs of different sizes and complexity, and different simulation assumptions. By trying to mimic previous results under diverse settings, we can show that the main advantage of our approach consists of making the modeling more flexible and less error prone, and therefore helps delineate the boundary conditions under which the biological conclusions based on simulations of Boolean network models are valid. At the same time, we also show that, with the use of fast and efficient ASP solvers, the computational efficiency of our method is in the same range as that of the most efficient dedicated methods for the simulation of Boolean network models and the calculation of their attractors.

## 2 METHODS AND MODELS

### 2.1 Boolean network modeling of GRNs

In our work, we adopt the definition of Boolean networks as described in Kauffman (1993): a Boolean network model consists of network elements (nodes, here representing structural and regulatory genes/proteins) which can either be active (ON) or inactive (OFF) and interactions between these elements (edges, which represent the directed regulatory interactions between the genes). We define two types of regulatory interactions between interacting nodes i.e. activation (up-regulation) and inhibition (down-regulation). The activation state of a certain node at a certain time step is determined by a logical function of the activation states at the previous time step of its interactors (where the interactors of a node are defined as the incoming edges of a certain network node).

Formally, a Boolean network model \(G(V, F)\) is defined by a set of nodes \(V = \{x_1, \ldots, x_n\}\) and a list of Boolean functions \(F = \{f_1, \ldots, f_n\}\). Each \(x_i \in \{0, 1\}\) is a binary variable and its value at time \(t+1\) can be determined by the values of some other nodes \(x_j\) at time \(t\) by means of a Boolean function \(f_i \in F\). That is, there are \(k_i\) nodes assigned to \(x_i\) that determine its state. The activation state of every node \(x_i\) changes over time according to

\[
x_i(t+1) = f_i(x_1(t), x_2(t), \ldots, x_k_i(t))
\]

A state \(s\) of a Boolean network is an assignment of \(\{0, 1\}\) to each node \(x_i\). Its successor state is the state resulting of applying \(f_i\) to each node \(x_i\). The dynamics of the network consists of transitions between network states. An example of a Boolean network is given in Figure 1. This network has 3 nodes, denoted by \(x_1, x_2\) and \(x_3\), and interactions between these nodes, represented by the edges. The dynamics of the network can be described using a State Transition Graph (STG) as given in the supplementary Figure S1.

Attractors in a Boolean network model are defined as in Garg et al. (2007) and Ay et al. (2009).
satisfied:

are repressing (inhibiting) links.

Fig. 1: A Boolean network model with three genes. Edges with arrowed tips are activating interactions and edges with blunt tips are repressing (inhibiting) links.

\[ \text{D}\text{EFINITION} \]

Let \( S \) be a set of states of a Boolean network model. \( S \) is an attractor if and only if the following conditions are satisfied:

1. The set of the successor states of all the states in \( S \) is equal to \( S \).
2. For each \( s_i \in S \), once it is visited, the probability of revisiting \( s_i \) in a finite number of state transitions is equal to 1.

2.2 Representing Boolean network models of GRNs and computing their attractors using ASP

**ASP-G framework**

Our framework for modeling GRNs and computing attractors, called ASP-G, uses Answer Set Programming (ASP). ASP is a declarative programming paradigm (Lifschitz (2008)), which is typically used to solve combinatorial search problems (Eiter et al. (2009)). The architecture of ASP-G is shown in Figure 2. ASP-G consists of four main modules/parts of the system: the network description, the update scheme, the activation rules and the attractor computation algorithm. The following describes each of these modules.

**Network description module**

This module contains the description of the structure of the network, encoded in a set of facts provided by the user. Because of the declarative nature of ASP, such a description can be written succinctly in an intuitive format. For example, the following set of facts is used to describe the network depicted in Figure 1:

\[
\begin{align*}
gene(x_1). & \quad gene(x_2). & \quad gene(x_3). \\
activates(x_1, x_1). & \quad activates(x_1, x_2). & \quad activates(x_1, x_3). \\
activates(x_2, x_1). & \quad activates(x_2, x_3). & \quad inhibits(x_3, x_1). \\
activates(x_3, x_2). & \quad inhibits(x_3, x_3).
\end{align*}
\]

To compare the declarative specification of the network with the more classically-used SAT notation Dubrova and Teslenko (2011), we give the network specification corresponding to the Boolean network depicted in in Figure 1 in cnet format, as follows:

\[
\begin{array}{cccccc}
.n & 1 & 3 & 1 & 2 & 3 \\
--1 & 0 & 1- & 1 & 1- & 0 \\
1-0 & 1 & -1 & 1 & 1-0 & 1 \\
-10 & 1 & 00 & 0 & -10 & 1 \\
000 & 0 & 000 & 0
\end{array}
\]

Each gene in the network is written with its label, e.g. \( n \) for node \( x_1 \), followed by the number of regulators and then their labels, e.g. \( 3 \ 1 \ 2 \ 3 \). Next a truth table follows that determines the behavior of the network (e.g. \(-1 \ 0 \) in the truth table for \( x_1 \) means that whenever \( x_3 \) is active then \( x_1 \) will be inhibited irrespective of the values of \( x_1 \) and \( x_2 \)).

**Activation rules**

This module determines the activation rules used to update the activation state of each gene at each transition step, based on the intended assumption by the user. We implemented two frequently used activation rules:

1. A gene will be active in a subsequent time step \( t + 1 \) if at time step \( t \) at least one active interactor is an activator and no active inhibitors that act as inhibitors are present.
2. A gene will be active in a subsequent time step \( t + 1 \) if there are more active activators than active inhibitors among its interactors at time step \( t \).

In ASP-G this first type of activation rule is encoded as

\[
r^+_1 : \text{active}(X, T) \leftarrow A > 0, I = 0, \#\text{act}(X, A, T - 1), \\
\#\text{inh}(X, I, T - 1), \text{gene}(X), \\
T > 0.
\]

The second type of activation rule is encoded as

\[
r^+_2 : \text{inhibited}(X, T) \leftarrow \text{not active}(X, T), \text{gene}(X), \\
T > 0.
\]
To illustrate the flexibility of ASP to express nearly any possible activation rule, we implemented a more specific type of rules in which the activation of a certain gene is expressed as a free-form gene-specific Boolean function of all the interactors of that gene, such as the one used in Sanchez-Corrales et al. (2010) and González et al. (2008). For example, the activation rule of a gene \( G_1 \) might be expressed as a Boolean function of the form:

\[
G_1 = G_1 \text{ and } (\neg G_2 \text{ or } \neg G_3)
\]

where \( G_2 \) and \( G_3 \) are two other genes involved in the network. In this case, \( G_1 \) has a self-activating interaction, while \( G_2 \) and \( G_3 \) act as inhibitors for \( G_1 \). To accommodate such an activation rule in ASP-G, we first convert the Boolean function into a Disjunctive Normal Form (DNF). For example, the activation rule given above is rewritten into the following:

\[
G_1 = G_1 \text{ and } \neg G_2
\]

\[
G_1 = G_1 \text{ and } \neg G_3
\]

and then encoded in ASP as follows:

\[
\text{active}(G_1, T) \leftarrow T > 0, \text{active}(G_1, T - 1),
\]

\[
\text{inhibited}(G_2, T - 1)
\]

\[
\text{active}(G_1, T) \leftarrow T > 0, \text{active}(G_1, T - 1),
\]

\[
\text{inhibited}(G_3, T - 1)
\]

Update scheme

Two update schemes were adopted in ASP-G: synchronous and asynchronous updates. In the synchronous update scheme, we assume that all genes in the network are updated simultaneously per evaluated time step. This implies that the transitions between the network states are deterministic, i.e., for every state visited over time, only one possible successor state exists. In the asynchronous update, no assumptions of synchronicity are made, and genes may be updated at different time steps. Therefore, transitions are non-deterministic; there may be several possible next states after a certain transition. As illustrated in the supplementary Figures S1 and S2, an asynchronous update scheme can result in a drastically different STG and leads to different attractors.

Both the synchronous and the asynchronous updating were implemented in ASP-G. For the synchronous update scheme, we use the following rules to generate initial activation states of the genes:

\[
\text{active}(X, 0) \leftarrow \text{gene}(X), \neg \text{inhibited}(X, 0).
\]

\[
\text{inhibited}(X, 0) \leftarrow \text{gene}(X), \neg \text{active}(X, 0).
\]

and then use the following rules (in relation with the activation rules described previously) to determine the activation state of each gene at each time step \( t \):

\[
\text{active}(X, t) \leftarrow \text{active}(X, t - 1), \neg \text{inhibited}(X, t).
\]

\[
\text{inhibited}(X, t) \leftarrow \text{inhibited}(X, t - 1), \neg \text{active}(X, t).
\]

For the asynchronous update scheme, we need to add the following rules, in addition to the previously described rules:

\[
\text{changed}(X, T) \leftarrow \text{active}(X, T), \neg \text{inhibited}(X, T - 1), \text{gene}(X), T > 0.
\]

\[
\text{changed}(X, T) \leftarrow \neg \text{inhibited}(X, T), \text{active}(X, T - 1), \text{gene}(X), T > 0.
\]

\[
\text{#changed}(N, X, T), N \geq 2, \text{gene}(X), T > 0.
\]

To obtain a better performance in the asynchronous case, we apply the STG reduction technique, as explained in the supplementary Figure S2.

Computing the attractors

The attractor computation in ASP-G is performed by Algorithm 1, which is based on the algorithm by Dubrova and Teslenko (2011). The main idea used in Algorithm 1 is to identify attractors by looking at identical states in transition paths of certain lengths in the STG of the network. Since there are exponentially many possible states in an STG (in relation to the number of nodes in the network), explicit enumeration of all the states in an STG is unfeasible for larger networks. ASP-G avoids this explicit enumeration by implicitly simulating the dynamics of the network. Furthermore, once a state is identified as part of an attractor, it can be removed from the STG to prune the search space. An illustration on how the algorithm works is given in supplementary Figure S4. Path generation and state removal are being done using ASP rules and ASP constraints, respectively, as shown in Figure S5. To further increase the efficiency of the computation, we use the incremental ASP approach described in Gebser et al. (2008b) and the clasp solver from the Potassco ASP suite (Gebser et al. (2011b)).

3 RESULTS

3.1 ASP-G: a novel framework for the simulation and attractor computation of GRNs with Boolean network models

Simulating Boolean network models implies that activation rules have to be defined to decide how a gene is activated by its interactors. The exact choice of the assumptions largely determines the outcome and the number and characteristics of the attractors. Supplementary Figures S1-S3 show that, for the example Boolean network in Figure 1, the choices of activation rules and update scheme can result in a different network behavior, and thus, different sets of attractors. As it is often not known in advance which assumptions best match the biological reality of the modeled GRN, testing different assumptions is advisable.

To have a generic framework that allows testing different assumptions, ASP-G implements three different activation rules: the first one adopted by Li et al. (2004), Ay et al. (2009) and Davidich and Bornholdt (2008) in which a gene is considered to be activated if the majority of its active incoming interactors (interactors that are themselves active) has an activating role. Otherwise, the gene will become inactive. This is referred to as the \( r^* \) rule in ASP-G. A second one adopted by Pedicini et al. (2010) and Garg et al.

\((2007)\) assumes that a gene is activated only when there is at least one active activator amongst its active incoming interactors and no inhibitor. This is referred to as the \( r^+ \) rule in ASP-G. In addition, we implemented a third more detailed activation rule in which the activation for each gene is expressed as a free-form Boolean function of its activators and inhibitors. This type of rules better grasps the complexity of true biological interactions and includes more detailed information on the specifics of the interactions. It was used in for instance Sanchez-Corrales \textit{et al.} (2010), Albert and Othmer (2003) and Gonzalez \textit{et al.} (2008).

Related to the update scheme, a choice has to be made between updating the network elements simultaneously (synchronously) versus at different points (asynchronously). Earlier work by Thomas (1973) and Kauffman (1993) assumed synchronicity in their modeling, mainly because of computational efficiency reasons. However, the assumption of synchronicity was challenged in Thomas (1991) and Harvey and Bossmairer (1997), who argued that, for many biological systems, assuming an asynchronous update scheme is more realistic. Subsequent work on Boolean network models (Naldi \textit{et al.} (2007), Garg \textit{et al.} (2007), Ay \textit{et al.} (2009), Garg \textit{et al.} (2008) and Gonzalez \textit{et al.} (2008)) mainly applied asynchronous update schemes. Therefore, in ASP-G we implemented both the synchronous and the asynchronous update scheme.

3.2 Simulation Results

To test the correctness of ASP-G in simulating Boolean network models and computing attractors, we applied ASP-G on previously published Boolean network models of GRNs and compared the obtained attractors with the originally published ones. Like any other formalism to find attractors in Boolean network models, ASP-G detects exhaustively all attractors of the network. Therefore, a correct result corresponds to an exact match in the attractor set identified by ASP-G and that present in the reference publications.

First we tested ASP-G on the relatively small GRNs involved in budding and fission yeast cell cycle analyzed in Li \textit{et al.} (2004), Ay \textit{et al.} (2009) and Davidich and Bornholdt (2008), as well as on the network model of the GRN from the Th cell differentiation described in Garg \textit{et al.} (2007). We used the activation rules and update schemes that were also applied in the original studies, except for the data set of Garg \textit{et al.} (2007), in which we applied also the synchronous update scheme in addition to the originally applied asynchronous one (see Table 1).

As expected for each of these results, the attractors found by ASP-G match exactly the ones found by the reference papers (data not shown). The table also shows that ASP-G performs relatively fast for these small networks. We also observe that the attractors in the synchronous case often coincide with those in the asynchronous case. This is due to the fact that simple attractors (i.e., attractors that have only one state) are more commonly found, and that they are shared between synchronous and asynchronous update schemes. Only for the fission yeast cell network under the \( r^+ \) activation rules there is a difference in the number of synchronous attractors (13) and asynchronous attractors (15). The fact that there are more attractors in the asynchronous case might seem counter-intuitive, since the reduced STG used to calculate these attractors contains at most as many nodes as the synchronous STG, and often less. However, the original STG for the asynchronous case typically contains more edges than in the synchronous case, and these additional edges can account for more attractors.

To show the flexibility of ASP-G in expressing different types of activation rules, we also encoded the Boolean network model of the GRN involved in \textit{A. thaliana} flower development originally described in Sanchez-Corrales \textit{et al.} (2010) with our ASP-G framework. This network model consists of 13 genes and uses gene specific update rules as described in Section 2.2 Activation rules. As in the original publication, we applied a synchronous update scheme. ASP-G correctly recapitulated all 10 attractors of the network as described in the original paper Sanchez-Corrales \textit{et al.} (2010). The computation took only 0.479 seconds.

To test ASP-G on a larger network, we use the network data from the T-helper (Th) cell differentiation described by Pedicini \textit{et al.} (2010). The purpose of the study was to find evidence supporting (or contradicting) the traditional view that the genes involved in the regulation of the two types of Th cells, Th1 and Th2, have counter-regulatory interaction. Similar to what has been done in Pedicini \textit{et al.} (2010), we first computed the attractors of the original network in the presence of all genes and then searched for attractors in different single-gene knock-out networks in \textit{silico} to test the effect of knocking out intracellular genes towards the attractors of the network. To show the added value of using different simulation assumptions, we also performed the computations using an asynchronous update mechanism, as opposed to only synchronous update scheme, as performed by Pedicini \textit{et al.} (2010). The results are presented in the supplementary Table \textit{S6}.

In terms of computational efficiency, the result shows that ASP-G is able to perform relatively well for the moderately-sized Th cell network. For the asynchronous case, attractor computation required
The main added value of ASP-G is in its declarativity and modularity: it allows users to easily test different update schemes and activation rules when simulating the dynamics of their Boolean network model by selecting and modifying the appropriate modules. In addition, the fact that ASP-G is based on a declarative language makes it less error prone than other approaches such as SAT which depend on the definition of difficult to interpret and tedious to construct truth tables. Using an underlying declarative programming paradigm also makes ASP-G easily extendable to other parameter settings. Decoupling the problem definition from its solution thus allows for a greater flexibility compared to other ad hoc systems such as genYsis (Garg et al. (2007)) and geneFAtt (Zheng et al. (2013)), where assumptions such as update scheme and activation rules are already built into the system.

We showed the correctness of ASP-G in simulating Boolean network models and obtaining attractors under different assumptions by successfully recapitulating the detection of attractors of previously published studies. Relying on a modular and flexible declarative programming paradigm definitely comes at the expense of being slower than the more dedicated systems to compute attractors, such as genYsis (Garg et al. (2007)) and geneFAtt (Zheng et al. (2013)). However, in terms of computational efficiency, ASP-G proved to be quite fast (for small networks i.e. up to 23 genes computations are below a second, for larger networks i.e. up to 51 genes, the longest computation time took under 4.5 minutes). Also, ongoing research in ASP solvers (Gebser et al. (2011a)) will make it possible for ASP to reach a point where it outperforms other logic paradigms. This is definitely the case when comparing ASP with Binary (or multiple) Decision Diagrams (Lee (1959)) used to calculate attractors in Boolean Networks models for GRNs (Arellano et al. (2011), Naldi et al. (2007)) as they suffer from memory explosion when the size of the network starts to become large (Clarke et al. (2001)).

For larger-sized networks, any exhaustive method will face a challenge, as the state space of the network increases exponentially w.r.t. the number of nodes in the network. When dealing with such large-sized networks, ASP-G can be utilized to obtain a first rough idea of the network dynamics, and then more methodical approaches can be applied to refine the results. As shown in the results, this combination of different methods is needed to get a more accurate understanding of the complex dynamics of biological systems.
larger networks, methods that avoid an exhaustive search as in Ay et al. (2009) might become more suitable under these conditions. Conclusively, ASP-G is tailored to simulate Boolean network models of GRNs and to compute attractors in a diagnostic manner.

Conclusively, ASP-G is tailored to simulate Boolean network models of GRNs and to compute attractors in a diagnostic manner. Where one wants to test different update schemes and activation rules in order to find the setting that best matches experimental data or to correctly delineate the boundary conditions under which the biological conclusions based on these simulations are valid.
